APPENDIX 1

THE PALYNOLOGY OF MORWONG - 1, GIPPSLAND BASIN.
by.
A. D. PARTRidge

## lNTRODUCTION

The spore-pollen zonation is based on well preserved and diverse assemblages from the sidewall cores. The same assemblages were recognised in the cuttings examined but these were not used in delimiting the zones because of the uncertainty of the depths owing to incorrect lag times.

The following spore-pollen zones are identified in Morwong-l:

| Zone | Depth in Feet |  | Age |
| :--- | :---: | :---: | :---: |
|  | Highest data Lowest data | Miocene |  |
| Triporopollenites bellus Zone | $5370-5418$ | Early Eocene |  |
| Malvacipollis diversus Zone | $\cdots$ | $5460-5746$ | Paleocene |

## COMMENTS

The palynological evidence indicates that the top of Latrobe Group unconformity lies between 5418 and 5460 feet and represents a time break from Early Eocene to Early Miocene.

Dinoflagellates dominate the palynological assemblages from the Lakes Entrance Formation and are absent or rare to common in assemblages from the Latrobe Group. In the latter those assemblages in which contain a high propotion of dinoflagellates are generally dominated by only a single species, either Cyclonopelium retiintextum or Wetzeliella homomorpha. Dinoflagellates were the only marine fossils found in the Latrobe Group and are probably indicative of only a very marginal marine environment.

Reworked Early Cretaceous spore-pollen are present in the L.balmei and T. bellus Zones. Paleocene and carly Eocene spore-pollen derived from the underlying Latrobe Group were also observed in the T bellus Zone.
 preserved and diverse assemblages containing common Lygistepollenites balmei. The top of the zone is taken at the extinction of Polycolpites langstonii, Gambierina rudata and the last common occurrence of

Australopollis obscurus and L.balmei.

The $M$. diversus Zone is recognised by the occurrence of Spinizonocolpites prominatus, Intratiporopollenites notabilis, Proteacidites grandis Polycolpites esobalteus and the absence of any younger species. The occurrence of $\underline{L}$. balmei and $\underset{A}{ }$. obscurus, indicator species for the underlying zone in the lowest sample ( 5746 feet) from the M . diversus Zone is considered to reflect the closeness of the zone boundary. The possibility of reworking is discounted because of the absence of other L. balmei Zone species while sample contamination has been checked for by reprocessing the sample.

The palynology assemblages between 5370 and 5418 feet are dominated by long ranging Oligocene-Miocene spore-pollen and dinoflagellate species which are referred to the T . bellus Zone on the basis of the occurrence of the spore Rugulatisporites micraulaxus;
