David Taylor

FORAMINIFERAL SEQUENCE

SWORDFISH # 1

by DAVID TAYLOR

Paleontology Report 1977/5 February 10, 1977

SUMMARY

The Swordfish # 1 well intersected a marine sequence from uppermost Eocene to Pliocene without any depositional breaks.

INTRODUCTION

Thirty nine side wall cores were examined between 3200 and 6698. No foraminifera were found in side wall cores at 3770, 4060, 6619, 6631, 6643, 6658, 6671, 6685, 6695 and 6698. Twenty nine rotary cutting samples were processed between 760 and 3040 and between 4100 and 4230 and the results incorporated in this report. Four rotary samples from 6490 to 6620 were examined also but as the depths were regarded as unreliable, the results have little significance. All depths cited in this report and listed in accompanying sheets are in feet.

The following sheets accompany this report:-

Distribution Chart Sheet 1 - showing distribution of planktonic foraminifera and the basis of biostratigraphic breakdown.

Distribution Chart Sheet 2 - giving the distribution of benthonic foraminifera.

Distribution Chart Sheet 3 - summarising the environmental analysis and presents an environmental interpretation.

Biostratigraphic Data Sheet

Two Sample Data Sheets

It is noted that the Salmon # 1 biostratigraphic data sheet has been revised.

BIOSTRATIGRAPHY

LATE EOCENE - 6604 to 6571:- Side wall cores contain a few specimens of *Globigerinatheka index* and *Subbotina linaperta* which are typical elements of the New Zealand late Eocene fauna. As this is the first report of *G. index* from Gippsland, it is difficult to place the fauna in the current zonal scheme. In Otway, the top of *G. index* was at the top of Zone L and preceded the top of *S. linaperta* which was at the top of Zone K. Jenkins (1974) disputes these observations as in New Zealand the tops of the ranges of both species were coeval. The fauna is definitely pre-J-2 and may represent Zone K if the sequence of faunal events was more akin to New Zealand than the Otway Basin. As there is no evidence of a depositional break between this late Eocene fauna and the overlying J-2 fauna, it is felt that the Swordfish # 1 late Eocene

assemblage represents Zone K of the Gippsland sequence, although it does not embrace the same biostratigraphic events as Zone K in the Otway Basin. Zone K in Swordfish # 1 can probably be equated with the lower part of the *G. brevis* Zone in New Zealand (Jenkins, l.c.) as it is succeeded almost immediately (= 7 feet between faunas) by Zone J-2 which contains a fauna identical to that in the upper part of the *G. brevis* Zone in New Zealand.

EARLY OLIGOCENE - 6564 to 6545:- Planktonic faunas in side wall cores of "greensand" at 6564 and 6560 include *Globigerina brevis* and *Tenuitella gemma* which are species which did not range above Zone J-2. The absence of *Globigerinatheka index* and *Subbotina linaperta* implies that this fauna can be equated with the upper part of the *G. brevis* Zone in New Zealand and was of early Oligocene age (Jenkins, l.c.).
The recrystallized limestone of the side wall core at 6545 bore a very poor fauna due probably to diagenetic obliteration. There were some recognisable specimens of *Subbotina angiporoides* which places the sample as being no younger than the top of Zone J.

LATE OLIGOCENE - ? to 6450:- Although the depth is disputed from evidence of E logs and side wall cores, rotary cuttings between 6490 and 6510 contain mixed faunas which include *Globigerina euapertura* and *Globorotalia opima opima*. The presence of these two species suggests that Zone I was within the section.
The side wall core at 6450 contains *Globoquadrina dehiscens* (s.l.), abundant *Globigerina woodi woodi* and rare *G. euapertura*. Such an association is now regarded as marking the very base of Zone H-2. This necessitates the revision of the Salmon # 1 section in that the base of Zone H-2 is now placed at the side wall core at 6236 so that the top of Zone I has been depressed.

EARLY MIOCENE - 6350 to 5750:- The fauna at 6350 has the lowest occurrence of *Globigerina woodi connecta* which places it at the base of Zone H-1. Jenkins (l.c.) assumes that the evolutionary appearance of *G. woodi connecta* marked the base of the early Miocene in the extra-tropical Austral region. This assumption is partially confirmed by the association of *G. woodi connecta* with *Globorotalia kugleri* in some off-shore Gippsland wells other than Swordfish # 1.
Zone G and Zone F faunas are present respectively at 5950 and 5850.

Zone E-2 and the top of the early Miocene is marked by the appearance of *Praeorbulina glomerosa curva* in the side wall core at 5750.

MID MIOCENE - 5650 to 2100:- Although the fauna is unrepresentative, the lowest Zone D-2 sample is probably at 5650. A more definite D-2 assemblage, with *Orbulina universa* and *Globorotalia peripheroronda* was present in side wall core at 5550. The top of Zone D-2 was placed at 4140 (= rotary cuttings) which suggests that there was a thicker development of the Zone in Swordfish # 1 than in Salmon # 1. Identical means of identifying the zonal top were used in both wells. Zone D-1 was consequently thinner in Swordfish than in Salmon. The top of Zone C and the top of the mid Miocene were placed at 2100 on the highest appearance of *Globorotalia mayeri* in rotary cuttings. This is approximately the same depth as in Salmon # 1.

LATE MIOCENE - 2000 to ? :- The association of *Globorotalia acostaensis* and *G. lenguaensis* in the absence of *G. mayeri* suggests that the rotary cutting sample at 2000 was at the base of Zone B-2 at the base of the late Miocene. Because of poor faunas it is impossible to fix the top of Zone B-2 and thus the top of the late Miocene, but this boundary was definitely below 1180.

PLIOCENE - ? to 1180 to ? :- *Globorotalia conomiozea* and *G. sphericomiozea* were present at 1180 (rotary cutting) indicating a position at the top of Zone B-1 within the early Pliocene.
At 1090 there was an unique association which was not represented in rotary cutting samples either above or below. This species association included *Globorotalia crassaformis* and *G. puncticulata* and may be an expression of the diversity peak seen in Flounder # 5 and Hapuku # 1 at the base of Zone A-4. Planktonic faunas above 1090 are much less diverse and contain neither of the above species.

ENVIRONMENT

Data relating to this interpretation is shown on Distribution Chart - Sheet 3 whilst benthonic foraminiferal distribution is given on Sheet 2.

It is very difficult to make an interpretation on the environment of the late Eocene as planktonic foraminifera were very rare and only one benthonic

specimen was recorded. This could mean the environmental extremes of either very deep conditions at or near the C.C.D. or that the planktonic forms were washed into a low salinity lagoonal or embayment environment.

The early Oligocene "greensands" bore a high percentage of planktonic foraminifera, although the faunas were relatively numerically sparse (planktonics = 80%, whilst total fauna approximated 100 specimens). The rare benthonic forms included *Cibicides brevoralis, C. perforatus* and *Vulvulina granulosa* which give the impression of a continental shelf situation. A transgressive invasion of oceanic waters may have been responsible for the high planktonic percentages. The diagenetic destruction of fauna in the limestone (6545) makes it impossible to speculate on the significance of the lithological change in the early Oligocene from "greensand" to limestone.

The late Oligocene and early Miocene sediments have a deep water aspect, not only in the dominance by planktonic forms, but by the presence of such benthonics as *Melonis pompiloides, Karreriella bradyi, Siphouvigerina proboscidae* and various morphologically simple arenaceous forms.

The mid Miocene Zone D-2 fauna (from 5650 to 4140) indicates deposition at the base of the continental slope with some evidence of sediment accumulation by down-slope slumping. One of the characteristic species of this interval is the large, costate *Euuvigerina maynii*.

The mid Miocene benthonic faunas between 4060 and 2820 have a low diversity and are probably the result of size and/or shape sorting. *Cassidulina carinata* dominates the benthonic fauna in some samples, with the flat *Cibicides thiara* almost ubiquitous. This sorting effect strongly suggests that the micritic limestone of this interval was a canyon fill.

Benthonic diversity increased at 2720 and faunas between there and 1700 (= Zone B) show a mixture of outer and inner continental shelf species including the seaweed adherent, *Cibicides cygnorum.* The faunal mixture and displacement of shallow water forms indicate that the sediment may have been deposited in a canyon head situation.

Above 1700 the fauna was dominated by *Cibicides* spp. and even higher (above 1000) by *Elphidium crassatum* and *Notorotalia clathrata*. This distribution pattern is evidence of gradual progradation from mid to

inner continental shelf during the latest Miocene and Pliocene. The benthonic faunal association between 1120 and 760 includes *Notorotalia clathrata, Parrellina imperatrix, Discoanomalina mitchelli* and *Valvulineria kalimnensis* and is a similar association to those described by Carter (1964) from the Tambo River and Jemmy Point Formations of the onshore Lakes Entrance region. However, the two onshore formations cannot be recognised in Swordfish # 1 either lithologically or on precise distribution of species; for instant, *V. kalimnensis* was confined to the Jemmy Point Formation whilst *Discoanomalina mitchelli* was restricted to the underlying Tambo River Formation, but both species were present in the same sample in Swordfish # 1. The richly bryozoal Pliocene calcarenites bearing this association in Swordfish were deposited in slightly deeper water than the marginal deposits around Lakes Entrance.
